Outline

• Study designs
• Observational vs. experimental studies
• Causal inference
• New approaches
• Causal information from health registry data
• Concluding remarks
Study designs

Epidemiological studies

Descriptive
- amount and distribution in populations
- person, place and time

Analytic
- test hypotheses
- identify and quantify risk or exposure

Descriptive Study Types
- case reports
- case series
- ecological studies
- cross sectional or prevalence surveys

Observational Study Types
- case-control
- cohort
- ecological studies
- cross sectional or prevalence surveys

Experimental Study Types
- clinical trials
- preventive trials
- community intervention trials

Observational vs. experimental studies: What is the evidence for a hierarchy?

- Often, a single RCT is considered to provide “truth” whereas results from any observational study are viewed with suspicion.
- We have a rigid hierarchy of research design that underestimates the limitations of randomized controlled trials, and overstates the limitations of observational studies.
- A more balanced and scientific justified approach is to evaluate the strengths and limitations of well done experimental and observational studies, recognizing the attributes of each type of design.

Concato J. NeuroRx 2004; 1: 341-7
Conclusions
The results of well-designed observational studies (with either a cohort or a case–control design) **do not systematically overestimate** the magnitude of the effects of treatment as compared with those in randomized, controlled trials on the same topic.

Observational studies suggested a protective effect of hormones on coronary heart disease, whereas randomised controlled trials pointed to no benefit, or even harm.

Table 1. Potential Explanations for Discordant Findings from Randomized Trials and Observational Studies Regarding Postmenopausal Hormone Therapy and Coronary Heart Disease.

| Hormone regimen (formulation and dose)          |   |
| Characteristics of study population (endogenous estrogen level, time since menopause, and stage of atherosclerosis) |   |

The observational studies and the randomized trials may be answering different questions

Study designs

- In observational studies, the researcher observes and systematically collects information, but does not try to change the people (or animals, or reagents) being observed.
- In an experiment, by contrast, the researcher intervenes to change something (e.g., gives some patients a drug) and then observes what happens.
- In an observational study there is no intervention.

Observational vs. experimental studies

- Experimental studies are ones where researchers introduce an intervention and study the effects.
- Observational studies are ones where researchers observe the effect of a risk factor, diagnostic test, treatment or other intervention without trying to change who is or isn’t exposed to it.
- Observational studies make use of careful measurement of pattern of exposure and disease in populations to draw inferences about etiology.
- In observational studies, the researcher is an observer rather than an agent who assigns interventions.

Observational studies

**COHORT STUDY**

- **Study Population**
  - Disease-free (at risk)
  - Population

  - **Cohort 1**
    - Exposed group
    - Disease
    - No Disease

  - **Cohort 2**
    - Unexposed group
    - Disease
    - No Disease

1. Identify exposed and unexposed cohort groups.
2a. PROSPECTIVE STUDY
   - During follow-up period, identify diseased subjects (incident cases).
2b. RETROSPECTIVE STUDY
   - Identify diseased subjects by interview or written records.
3. Analyze differences (i.e., incidence or relative risk) among those exposed (cohort 1) and those unexposed (cohort 2).

**CASE-CONTROL STUDY**

- **Cases**
  - (Outcome present)
  - Exposure present
  - Exposure absent

- **Controls**
  - (Outcome absent)
  - Exposure present
  - Exposure absent

1. Identify cases.
2. Select controls, which may be matched to cases.
3. Measure exposure or risk factors of interest.
4. Compare the presence or absence of exposure in cases and controls.
Exposure → Effect → Outcome

Bias / confounding
Validity

**Internal validity** implies that there is no bias in the way the data is collected, analysed and interpreted.

**External validity** is the generalizability of the study results to subjects out of the study sample.
Limitations of observational studies

«All observational studies have one crucial deficiency: The design is not an experimental one.»

Pocock SJ et al. NEJM 2000; 342: 1907-9

https://www.inference.vc/
Confounding («traditional thinking»)

- Confounding is a term used to describe distortion of the estimate of the effect of an exposure of interest because it is mixed with the effect of an extraneous factor.
- To be a confounder, the extraneous factor must satisfy the following three criteria:
  1. Be a risk factor for the disease.
  2. Be associated with the exposure under study in the population from which the cases derive.
  3. Not be an intermediate step in the causal path between exposure and disease.

Friis RH and Sellers TH, Epidemiology for Public Health Practice, 2009
Confounder and collider (DAGs)

C is a common cause of E and D
Confounder

C is a common effect of E and D
Collider bias / selection bias
Bias

• **Selection bias** arises when the relation between exposure and disease is different for those who participate and those who would be theoretically eligible for study but do not participate.

• **Information bias** is a kind of bias introduced as a result of measurement error in assessment of both exposure and disease.

Friis RH and Sellers TH, Epidemiology for Public Health Practice, 2009
### Table 2. Advantages and Disadvantages of the Cohort Study

| Advantages                                                                 |                                                                                          |
|                                                                          | Gather data regarding sequence of events; can assess causality                            |
|                                                                          | Examine multiple outcomes for a given exposure                                           |
|                                                                          | Good for investigating rare exposures                                                    |
|                                                                          | Can calculate rates of disease in exposed and unexposed individuals over time (e.g., incidence, relative risk) |
| Disadvantages                                                            | Large numbers of subjects are required to study rare exposures                            |
|                                                                          | Susceptible to selection bias                                                              |
| Prospective cohort study                                                 | May be expensive to conduct                                                                |
|                                                                          | May require long durations for follow-up                                                  |
|                                                                          | Maintaining follow-up may be difficult                                                    |
|                                                                          | Susceptible to loss to follow-up or withdrawals                                          |
| Retrospective cohort study                                               | Susceptible to recall bias or information bias                                            |
|                                                                          | Less control over variables                                                               |

### Table 4. Advantages and Disadvantages of the Case-Control Study

| Advantages                                                                 |                                                                                          |
|                                                                          | Good for examining rare outcomes or outcomes with long latency                            |
|                                                                          | Relatively quick to conduct                                                              |
|                                                                          | Relatively inexpensive                                                                   |
|                                                                          | Requires comparatively few subjects                                                      |
|                                                                          | Existing records can be used                                                             |
|                                                                          | Multiple exposures or risk factors can be examined                                       |
| Disadvantages                                                            | Susceptible to recall bias or information bias                                            |
|                                                                          | Difficult to validate information                                                        |
|                                                                          | Control of extraneous variables may be incomplete                                       |
|                                                                          | Selection of an appropriate comparison group may be difficult                            |
|                                                                          | Rates of disease in exposed and unexposed individuals cannot be determined               |
When to perform observational studies?

- When an experiment would be **impractical, unethical or infeasible**.
- Randomised treatment assigns has important conceptual strengths, especially for reducing bias, but it is **resource intensive** and often applied to **highly selected populations**, making generalizations difficult.
- The central tasks of observational epidemiology are to build **theoretical understanding of causal mechanisms**, identify opportunities to test and revise theories, and provide reliable evidence that can **serve as a basis** for making decisions about clinical or population-health interventions.
- To achieve relevance, we need **better alignment between observational studies and potential next steps**, which might include RCTs, development of clinical guidelines, informing individual behavioral decisions, or institutional or governmental policy changes.

Bradford Hill criteria for evidence of causation

1) Strength of association
2) Consistency
3) Specificity
4) Temporality
5) Biologic gradient
6) Plausibility
7) Coherence
8) Experiment
9) Analogy

The decisive question is whether the frequency of the undesirable event B would be influenced by a change in the environmental feature A.
Causal inference in epidemiology

- The analysis of data from epidemiological and clinical studies is undergoing fundamental changes
- More studies include extensive data collected over time than has previously been the case
- Causal modeling has become a major topic in epidemiology, with emphasis on graphical models, Bayesian networks and counterfactual models

→ A systematic approach to evaluate causality
Causal inference – new methods

• Counterfactual thinking (Robins JS)
• Seeing vs. doing (Pearl J)
• The importance of time (Aalen O)
• Direct and indirect effects (Cole SR, Hernan MA)

RCTs, observational studies and causal inference

- The RCT has long been seen as the gold standard for causal inference in medical research. In RCTs, the patients are randomly assigned to different groups (treatment and control group). The resulting effect estimate is the difference between the mean response in the two groups.

- The ideal set-up can be violated for many reasons; perfect control over patients is hard to achieve, randomization into placebo groups is not always ethical, and the presence of the randomization itself might influence the participation in the study. In other words, it is not always feasible to create a RCT.

- Observational studies have the same goal as the RCTs, but differ in that the investigator cannot control treatment assignment.

- Observational studies are often the only alternative for causal inference, and methods exist that permit the estimation of causal treatment effects from observational data, under certain assumptions.
Contrafactual thinking

• The view on causality that is most natural in medicine is the contrafactual one.
• What would have happened if the intervention had not been made (or a different intervention had been made)?
• One compares the actual situation (with intervention) with the counterfactual one (without intervention) to see the causal effect of the intervention.
• The counterfactual factual world is carefully chosen under the assumption that all else should be equal except the condition under study.
Directed acyclic graphs (DAGs)

- are often used to provide a graphical representation of the conditional independencies or causal relations between random variables
- serve as a powerful tool when looking at causal systems and come with strategies for how to estimate effects between them
- are helpful for understanding of key concepts such as confounding and selection bias, and in the process of selecting the variables to include in statistical models
Directed acyclic graphs (DAGs)

- A DAG displays assumptions about the relationship between variables (often called nodes in the context of graphs). The assumptions we make take the form of lines (or edges) going from one node to another. These edges are directed, which means to say that they have a single arrowhead indicating their effect.
- A DAG is also acyclic, which means that there are no feedback loops.

A causal DAG for the variables $A$ and $Y$, with a confounding variable $L$. 

Four types of causal structures

**Figure 15.5** Association and possible causal structures between yellow fingers and lung cancer.
Directed acyclic graphs (DAGs)

FIGURE 1
A directed acyclic graph showing confounding and mediating factors in the current study associated with ART and childhood cancer. Covariates in red indicate that they have been classified as confounding factors; covariates in blue have been classified as intermediate factors.

Approaches to causal inference

- **Triangulation** is the practice of obtaining more reliable answers to research questions through *integrating results from several different approaches*, where each approach has different key sources of potential bias that are unrelated to each other.

- With respect to causal questions in aetiological epidemiology, if the results of different approaches all point to the same conclusion, this strengthens confidence in the finding.

- This is particularly the case when the key sources of bias of some of the approaches would predict that findings would point in opposite directions if they were due to such biases.

- Where there are inconsistencies, understanding the key sources of bias of each approach can help to identify what further research is required to address the causal question.
Repeating experiments is not enough

Verifying results requires disparate lines of evidence — a technique called triangulation. Marcus R. Munafò and George Davey Smith explain.
“We believe that an essential protection against flawed ideas is triangulation.

- This is the strategic use of multiple approaches to address one question.
- Each approach has its own unrelated assumptions, strengths and weaknesses.
- Results that agree across different methodologies are less likely to be artefacts.”

Nature 2018; 553: 399

---

**TRIANGULATION**

**A checklist.**

- The different approaches address the same underlying question.
- The key sources of bias for each approach are explicitly acknowledged.
- For each approach, the expected directions of all key sources of potential bias are made explicit, where feasible.
- Ideally, some of the approaches being compared will have potential biases that are in opposite directions.
- Ideally, results from more than two approaches — which have different and unrelated key sources of potential biases — are compared. *Source: ref. 3*
Triangulation – different approaches

- Conventional approaches
  - RCTs, multiple regression in observational data

- Refinements using general populations
  - Cross-context comparisons, different control groups, natural experiments

- Refinements using specific populations
  - Within sibling comparisons

- Refinements of exposure
  - Instrument variable (IV) analysis, IVs to test intermediates in RCTs, genetic IVs in observational data, non-genetic IVs in observational data, exposure negative control studies

- Refinements of outcome
  - Outcome negative control studies

Family-based design

- Sibling comparison designs
  - Twins, full siblings, and half-siblings are increasingly used as comparison groups in matched cohort and matched case-control studies
  - The «within-pair» estimates acquired through these comparisons are free from confounding from all factors that are shared by the siblings

Family-based design

GRANDMA + GRANDPA

Jacob + Anne  Sophie + Tom

Bob  Eve  Peter  Janet

Sibling pair  Cousin pair

Association within family analyses: **full siblings**, half-siblings, **full cousins** and half-cousins
Instrument variable analysis

• A method to control for unmeasured confounding in observational studies

• If an instrument Z for A exists, one can test for a causal effect of A on Y

• Z is a valid instrument for A if
  – Z affects A
  – Z affects A only through A, and
  – Z and Y share no common causes

A causal DAG for the variables A and Y, with an unmeasured confounding variable U and an instrument Z
Mendelian randomization (MR) analysis

- Mendelian randomisation is a research method that provides evidence about putative causal relations between modifiable risk factors and disease, using genetic variants as natural experiments.
- Mendelian randomisation is less likely to be affected by confounding or reverse causation than conventional observational studies.
- Like all analytical approaches, however, Mendelian randomisation depends on assumptions, and the plausibility of these assumptions must be assessed.
- Moreover, the relevance of the results for clinical decisions should be interpreted in light of other sources of evidence.

Davies NM, et al. BMJ 2018; 362: k601
Mendelian randomization

- Mendelian randomisation is a recent development in genetic epidemiology based on Mendel's second law that inheritance of one trait is independent of inheritance of other traits.
- It uses common genetic polymorphisms that are known to influence exposure patterns (such as propensity to drink alcohol) or have effects equivalent to those produced by modifiable exposures (such as raised blood cholesterol concentration).
- Associations between genetic variants and outcome are not generally confounded by behavioural or environmental exposures.
- This means that observational studies of genetic variants have similar properties to intention to treat analyses in randomised controlled trials.

Comparison of design

Mendelian randomisation

Random segregation of alleles

Exposed: one allele
Control: other allele

Confounders equal between groups

Outcomes compared between groups

Randomised controlled trial

Randomisation method

Exposed: intervention
Control: no intervention

Confounders equal between groups

Outcomes compared between groups

Mendelian randomisation studies sit at the interface of experimental and observational studies. Their findings can be used to provide more reliable evidence to guide interventional research and provide information about potential public health interventions when a randomised controlled trial may not be feasible.
Propensity score (PS) analysis

- Propensity score (PS) analysis of observational studies is an alternative method of estimating causal treatment effects for clinically important questions in observational studies.
- PS analysis is a causal inference technique for treatment effect estimation in observational studies by accounting for the conditional probability of treatment selection, thus allowing for reduction of bias when comparing interventions between treatment arms.

Propensity score (PS) analysis

- In 1983, alternative methods for control of confounding in observational studies based on the propensity score were proposed.
- The propensity score is the probability that an individual would have been treated based on that individual’s observed pretreatment variables.
- Adjustments using the estimated propensity score tend to balance observed covariates that were used to construct the score.
- Several adjustment methods incorporating the estimated propensity score have been proposed, including matching, regression adjustment, and weighting.

Propensity score

• The propensity score is the probability that an individual would have been treated based on that individual’s observed pretreatment variables.

• The propensity score $e(X)$ for an individual is defined as the conditional probability of being treated given his or her covariates.

• $X: e(X) = \Pr(Z = 1 \mid X)$. 

Sensitivity Analysis in Observational Research: Introducing the E-Value

Tyler J. VanderWeele, PhD, and Peng Ding, PhD

Sensitivity analysis is useful in assessing how robust an association is to potential unmeasured or uncontrolled confounding. This article introduces a new measure called the “E-value,” which is related to the evidence for causality in observational studies that are potentially subject to confounding. The E-value is defined as the minimum strength of association, on the risk ratio scale, that an unmeasured confounder would need to have with both the treatment and the outcome to fully explain away a specific treatment-outcome association, conditional on the measured covariates. A large E-value implies that considerable unmeasured confounding would be needed to explain away an effect estimate. A small E-value implies little unmeasured confounding would be needed to explain away an effect estimate.

The authors propose that in all observational studies intended to produce evidence for causality, the E-value be reported or some other sensitivity analysis be used. They suggest calculating the E-value for any study of interest, and present a simple method for approximating the E-value. A central challenge in observational studies of causality is understanding the extent to which unmeasured factors may bias the results. The E-value is designed to provide a simple, intuitive, and informative measure for this purpose.

\[ \text{E-value} = \text{RR} + \sqrt{\text{RR} \times (\text{RR} - 1)} \]

Figure 2. Value of the joint minimum strength of association on the risk ratio scale that an unmeasured confounder must have with the treatment and outcome to fully explain away an observed treatment-outcome risk ratio of RR = 3.9, as in the study by Victora and colleagues (23).
The E-value

- The E-value is an alternative approach to sensitivity analyses for unmeasured confounding in observational studies that avoids making assumptions.
- An E-value analysis asks the question: How strong would the unmeasured confounding have to be to negate the observed results?
- The E-value itself answers this question by quantifying the minimum strength of association on the risk ratio scale that an unmeasured confounder must have with both the treatment and outcome, while simultaneously considering the measured covariates, to negate the observed treatment–outcome association.
- If the strength of unmeasured confounding is weaker than indicated by the E-value, then the main study result could not be overturned to one of “no association” (ie, moving the estimated risk ratio to 1.0) by the unmeasured confounder.
- E-values can therefore help assess the robustness of the main study result by considering whether unmeasured confounding of this magnitude is plausible.
- The E-value provides a measure related to the evidence for causality, hence the name “E-value.”

The E-value: Advantages

• It requires no assumptions
• It is intuitive because the lowest possible number is 1
  – The higher the E-value is, the stronger the unmeasured confounding must be to explain the observed association
• The calculation is also readily applied to the bounds of a 95%CI
  – Investigators can assess the extent of unmeasured confounding that would be required to shift the CI so that it includes a risk ratio of 1.0 (ie. no association)
• The E-value is simple to calculate for a range of effect measures and study designs

### STROBE Statement

**What is STROBE?**

STROBE stands for a collaborative initiative of epidemiologists, researchers, and journal editors aimed at improving the quality of reporting of observational studies in epidemiology.

---

#### Introduction

- **Background rationale**: Explain the scientific background and rationale for the investigation being reported.
- **Objectives**: State specific objectives, including any pre-specified hypotheses.

#### Methods

- **Study design**: Present the key elements of study design early in the paper.
- **Setting**: Describe the setting, location, and relevant dates, including periods of recruitment, exposure, follow-up, and data collection.

#### Participants

- **Eligibility criteria**: Give the eligibility criteria and the sources and methods of selection of participants.
- **Methods of follow-up**: Describe methods of follow-up.
- **Case-control studies**: Give the eligibility criteria, and the sources and methods of case ascertainment and control selection.
- **Cross-sectional studies**: Give the eligibility criteria, and the sources and methods of selection of participants.

#### Variables

- **Outcome, exposure, predictors, confounders, and effect modifiers**: Give diagnostic systems, if applicable.
- **Data sources/measurement**: For each variable of interest, give sources of data and details of methods of measurement. Describe comparability of measurement methods if there is more than one group.

#### Bias

- **Describe any efforts to address potential sources of bias**.

#### Study size

- **Explain how the study size was arrived at**.

#### Quantitative variables

- **Explain how quantitative variables were handled in the analyses**: If applicable, describe which groupings were chosen and why.

#### Statistical methods

- **Describe all statistical methods, including those used to control for confounding**: (a) Describe any methods used to examine subgroups and interactions.
- **Explain how missing data were addressed**: (d) In case-control studies, if applicable, explain how loss to follow-up was addressed.

---

**STROBE Statement—checklist of items that should be included in reports of observational studies**

Evidence-Based Medicine in Surgery
The Importance of Both Experimental and Observational Study Designs

Ryan P. Merkow, MD
Clifford Y. Ko, MD, MS, MSHS

section and radiation therapy did not lead to worse outcomes compared with total mastectomy. More recently, the NSABP B-32 trial demonstrated the efficacy of sentinel lymph
The importance of both experimental and observational study designs

• Results from RCTs have changed breast cancer care, saving countless of women from undergoing radical surgery
• The significance of occult micrometastasis in sentinel lymph nodes and bone marrow in women with early stage disease was addressed observationally with a prospective cohort study design
• Occult bone marrow metastases was no longer associated with decreased survival after adjustment

Merkow RP, et el. JAMA 2011; 306: 436-7
The importance of both experimental and observational study designs

• The observational study
  – offers a clear example of how well-designed observational studies can address relevant clinical questions
  – provides significant insight that will help guide daily treatment decisions

Merkow RP, et el. JAMA 2011; 306: 436-7
The importance of both experimental and observational study designs

• To account for the potential limitations of observational studies, investigators can use several statistical and methodological techniques

• In a retrospective cohort study, designed to investigate long-term outcomes after bariatric surgery among high-risk veterans, the authors compared survival after bariatric surgery with outcomes in high-risk controls, both in unmatched and propensity-matched cohorts

• The survival advantage observed in the unmatched cohort (adjusted HR 0.80; 95% CI, 0.63-0.995) disappeared in the propensity score–matched cohort (adjusted HR, 0.94; 95% CI, 0.64-1.39)

Maciejewski ML, et al. JAMA 2011; 305: 2419-26
From randomized controlled trials to observational studies

- Randomized controlled trials are considered the gold standard in the hierarchy of research designs for evaluating the efficacy and safety of a treatment intervention.
- However, their results can have limited applicability to patients in clinical settings.
- Observational studies using large health care databases can complement findings from randomized controlled trials by assessing treatment effectiveness in patients encountered in day-to-day clinical practice.
- Results from these designs can expand upon outcomes of randomized controlled trials because of the use of larger and more diverse patient populations with common comorbidities and longer follow-up periods.
- Furthermore, well-designed observational studies can identify clinically important differences among therapeutic options and provide data on long-term drug effectiveness and safety.

When an Entire Country Is a Cohort

«It is a moral obligation to exploit data gathered at great expense.»

«Would it not be unethical not to use it to improve the populations’s health and health care?»
National health registries

• The mandatory national health registries were established to maintain national functions. They are used for health analysis, health statistics, improving the quality of healthcare, research, administration and emergency preparedness.

• Can we derive causal information from the nationwide health registries?
The Nordic countries have special preconditions for conducting large population-based studies

- the populations are relatively homogeneous (being genetically reasonably similar with quite similar lifestyles)
- the individuals have free access to public health services
- nation-wide registers have been running for decades
- every resident has a unique personal identification number (country-specific) that is used by the registries, making precise record linkages possible
- a strict confidentiality and data protection legislation allows the use of health registry data for research purposes

Sankila R. Maturitas 2010; 66; 180-1

Sudden infant death syndrome (SIDS) and sleeping position

Data

- Time trend in SIDS from the Medical Birth Registry of Norway
- Exposure from ad hoc survey in 1992
- Time trend in retrospectively reported sleeping position in 1992 for the years 1970, 75, 80, 85, 89, 90, 91 by 24438 mothers (70% response rate) sampled from 20 largest maternity institutions
- For each year and institution 250 mothers were randomly selected 7x20x250=35,000
- One page questionnaire
- 92.5% stated they were certain about the babies sleeping position at 3 months of age

Risk of Fetal Death after Pandemic Influenza Virus Infection or Vaccination

Siri E. Håberg, M.D., Ph.D., Lil Trogstad, M.D., Ph.D., Nina Gunnes, Ph.D., Allen J. Wilcox, M.D., Ph.D., Håkon K. Gjessing, Ph.D., Sven Ove Samuelsen, Ph.D., Anders Skrondal, Ph.D., Inger Cappelen, Ph.D., Anders Engeland, Ph.D., Preben Aavitsland, M.D., Steinar Madsen, M.D., Ingebjørg Buajordet, Ph.D., Kari Furu, Ph.D., Per Nafstad, M.D., Ph.D., Stein Emil Vollset, M.D., Dr.P.H., Berit Feiring, M.Sc.Pharm., Hanne Nøkleby, M.D., Per Magnus, M.D., Ph.D., and Camilla Stoltenberg, M.D., Ph.D.

BACKGROUND

During the 2009 influenza A (H1N1) pandemic, pregnant women were at risk for severe influenza illness. This concern was complicated by questions about vaccine safety in pregnant women that were raised by anecdotal reports of fetal deaths after vaccination.
Surveillance System of Infectious Diseases (MSIS)
- Positive H1N1 tests

Medical Birth Registry of Norway (MBRN)
- Pregnancy outcomes
- Chronic conditions in pregnant women

Population Registry of Norway

Immunzation Registry (SYSVAK)
- Vaccination status
- Date of vaccination

HELFO-data
Reimbursement of doctors (KUHR)
- Primary care consultations
- Influenza (R80)

Håberg SE, et al. NEJM 2013; 368: 333-40
CONCLUSIONS

Pandemic influenza virus infection in pregnancy was associated with an increased risk of fetal death. Vaccination during pregnancy reduced the risk of an influenza diagnosis. Vaccination itself was not associated with increased fetal mortality and may have reduced the risk of influenza-related fetal death during the pandemic.
Long-Term Colorectal-Cancer Mortality after Adenoma Removal

Magnus Løberg, M.D., Mette Kalager, M.D., Ph.D., Øyvind Holme, M.D., Geir Hoff, M.D., Ph.D., Hans-Olov Adami, M.D., Ph.D., and Michael Bretthauer, M.D., Ph.D.

CONCLUSIONS

After a median of 7.7 years of follow-up, colorectal-cancer mortality was lower among patients who had had low-risk adenomas removed and moderately higher among those who had had high-risk adenomas removed, as compared with the general population. (Funded by the Norwegian Cancer Society and others.)

β-Blocker Use in Pregnancy and the Risk for Congenital Malformations
An International Cohort Study

Brian T. Bateman, MD, MSc; Uffe Heide-Jørgensen, MSc, PhD; Kristjana Einarsson, PhD; Anders Engeland, MSc, PhD;
Kari Furu, MScPharm, MPH, PhD; Mika Gissler, PhD; Sonia Hernandez-Diaz, MD, DrPH; Helle Kieler, MD, PhD;

Randi Selmer, MSc, PhD; Krista F. Huybrechts, MS, PhD; and Helga Zoega, MA, PhD

Background: β-Blockers are a class of antihypertensive medications that are commonly used in pregnancy.

Objective: To estimate the risks for major congenital malformations associated with first-trimester exposure to β-blockers.

Design: Cohort study.

Setting: Health registries in the 5 Nordic countries and the U.S. Medicaid database.

Patients: Pregnant women with a diagnosis of hypertension and their offspring.

Measurements: First-trimester exposure to β-blockers was assessed. Outcomes were any major congenital malformation, cardiac malformations, cleft lip or palate, and central nervous system (CNS) malformations. Propensity score stratification was used to control for potential confounders.

Results: Of 3577 women with hypertensive pregnancies in the Nordic cohort and 14,900 in the U.S. cohort, 82 (19.1%) and 1668 (11.2%), respectively, were exposed to β-blockers in the first trimester. The pooled adjusted relative risk (RR) and risk difference per 1000 persons exposed (RD1000) associated with β-blockers were 1.07 (95% CI, 0.89 to 1.30) and 3.0 (CI, −6.6 to 12.6), respectively, for any major malformation; 1.12 (CI, 0.83 to 1.51) and 2.1 (CI, −4.3 to 8.4) for any cardiac malformation; and 1.97 (CI, 0.74 to 5.25) and 1.0 (CI, −0.9 to 3.0) for cleft lip or palate. For CNS malformations, the adjusted RR was 1.37 (CI, 0.58 to 3.25) and the RD1000 was 1.0 (CI, −2.0 to 4.0) (based on U.S. cohort data only).

Limitation: Analysis was restricted to live births, exposure was based on dispensed medication, and cleft lip or palate and CNS malformations had few outcomes.

Conclusion: The results suggest that maternal use of β-blockers in the first trimester is not associated with a large increase in the risk for overall malformations or cardiac malformations, independent of measured confounders.

Other large data sources

Clinical quality registries, large cohorts, and biobanks (associated with cohorts) are designed to study causes of diseases and to identify best treatments.
Why (or when) is observational better than experimental epidemiology?
Conclusions / key points

• when RCTs are impractical, unethical, infeasible or costly
• huge data sources (national registry data)
• use of advanced designs, methods and modelling
• real-life experiences and long follow-up
